Abstract

*Chlamydia trachomatis* (CT) is the most frequently detected agent of sexually transmitted infections worldwide. It is an obligate intracellular bacteria. CT infection of the lower female genital tract (FGT) can cause cervicitis and if ascending to the upper FGT may result in serious sequelae such as pelvic inflammatory disease, salpingitis and tubal factor infertility.

The purpose of this prospective study is the detection of CT antigen in cervical secretions and serum antibodies in infertile females undergoing intracytoplasmic sperm injection (ICSI).

The study was carried out at Tanta University Hospital in a period from June 2017 to September 2018. It was a prospective observational study, including 40 infertile females undergoing ICSI (patient group), and 20 multiparous women attending the outpatient clinic for contraception (control group).

We found that only 7.5% of the study group were positive for serum IgG compared with 20% of the control group. Further, in the study group, we found that serum IgM was found positive only in 5% in both studied groups. Similarly, Chlamydia antigen the cervical swab was detected in 5% of both the study and control group.

The very low prevalence rate of *Chlamydia trachomatis* infection in Egyptian females is justifiable by the cultural and religious impact on the sexual lifestyle in the Egyptian population. This low prevalence rate of CT infection in Egyptian females minimizes its role as a cause of infertility in the Egyptian population.

Keywords: Gynecology; Inflammatory Disease; Hypertension; Renal Disease; Systemic lupus.

Introduction

*Chlamydia trachomatis* is the most frequently detected agent of sexually transmitted infections worldwide. It is an obligate intracellular bacteria. They live in an intracellular vacuole that they customize to permit delivery of nutrients and to provide protection against host cell defenses [1].

According to recently published data, global estimates show that at least 100 million are estimated to be infections with *C. trachomatis* [2]. The prevalence of chlamydial infections was found to be 1.7% in 14–39-year-old women, but 4.7% of sexually active 14–24-year-old women [3]. Therefore, annual screening in females <25 years is strongly recommended [4].
Patients and Methods

The study was carried out at Tanta University Hospital in a period from June 2017 to September 2018. It was a prospective observational study, including 40 infertile females undergoing ICSI (patient's group), and 20 multiparous women attending the outpatient clinic for contraception (control group).

Patients were counseled before participation in this study, explanation, and notification of the procedures and its aim was done and a written informed consents were taken from all the patients.

The study protocol was approved by the local research and ethics committee in Tanta University Hospital. There were adequate provisions to maintain the privacy of participants and confidentiality of the data, the patient’s name was replaced by a serial number & her address was confidential.

Inclusion criteria

- Age range between 25 and 39 years.
- Duration of infertility for more than 2 years.

Exclusion criteria

- Systemic diseases such as diabetes mellitus, hypertension, renal disease & systemic lupus.
- Local diseases such as a fibroid, uterine anomalies as uterine septum or adenomyosis.
- Moderate to severe endometriosis.
- The severe male factor of the male partner (count of sperm less than 5 million/ml, abnormal forms of sperms more than 90% and motility less than 10%).

All cases in this study were subjected to the following: Complete history taking, clinical examination, and investigations including:

- FSH, LH, E2 were done on cycle day 3 for all cases, those with abnormal results were excluded.
- T3, T4, TSH, Prolactin were normal in all cases, those with abnormal results were excluded.
- Transvaginal ultrasound.
- Hysterosalpingography.
- Cervico-vaginal secretion sample was collected after cleaning of the cervical canal from mucus for detection of Chlamydia trachomatis antigen by the direct binding monoclonal-based immunochromatographic assay [18].
- Two ml venous blood were withdrawn and serum was separated for detection of Chlamydia antibodies (IgG & IgM) using ELISA [19].
- ICSI procedures:

Patients underwent controlled ovarian stimulation using the long agonist protocol for pituitary down-regulation. Ovarian stimulation was carried out with:

I. Recombinant follicle stimulating hormone (rFSH) alone.
II. Highly purified human menopausal gonadotropin (HP-HMG) alone. or
III. rFSH combined with HP-HMG.
The initial dose of gonadotropin was individualized for each patient according to age, basal FSH levels, antral follicular count, BMI and previous response to controlled ovarian stimulation. Dose adjustment was performed according to ovarian response and monitored by means of the vaginal scan [20,21].

The Statistical Package for Social Science (SPSS) was utilized for statistical analysis and tabulation. The following statistical measures were used: Descriptive measures included: count, percentage, minimum, maximum, arithmetic mean and standard deviation. Statistical tests included: Student t test, [22] Chi-square test [23]. The level of significant selected for this study was P less than or equal to 0.05.

Results

This work was carried out on 60 married women dividing into two groups: Study group included 40 females attending fertility clinics for the management of infertility, while a group comprising 20 multiparous females attending the outpatient clinic asking for contraception (a control group). The outcomes of this study are revealed in 6 tables and 2 figures.

Table 1 displays the clinical data of the examined cases. Where as table 2 provides evidence that there were only 3 positive cases for serum IgG in the study group (7.5%) and 4 positive cases in the control group (20%). Further, in the study group, we found that serum IgM was found positive only in 2 cases (5%), while in the control group it was positive in one case (5%). Chlamydia antigen the cervical swab was detected in 2 cases (5%) in the study group, and in one case in the control group (5%). At that place was no statistical significant difference between the survey and control groups regarding chlamydial antigen positivity.

Table 3 and figure 1 demonstrate that the most common cause (32.5%) for infertility was Polycystic Ovaries (PCOS), while the endometriosis was the least (5%). It was also found that there were 8 cases with unexplained cause.

Table 4 shows that by analyzing the pregnancy outcome of the study group cases after ICSI, it was found that there were 13 cases (32.5%) were positive for a pregnancy test (quantitative B-hCG).

Table 5 illustrates the relation between pregnancy outcome of the study group cases after ICSI, it was found that there were 13 cases (32.5%) were positive for a pregnancy test (quantitative B-hCG).

Table 6 shows pregnancy after ICSI in the study group. It was found that 13 cases (34.21%) of cases negative for chlamydia antigen were positive pregnancy test. There were no cases with positive chlamydia antigen got pregnant.

Figure 2 illustrates the relation between chlamydia antigen detection and serum IgM & IgG in the study group.

**Discussion**

Preexisting asymptomatic infections with chlamydia trachomatis can be disseminated when infertile patients undergo ICSI, hence, the Royal College of Obstetricians and Gynecologists recommends that all patients undergoing ICSI should be screened for Chlamydia or should have preventive antibiotics [24].

Seropositive women for Chlamydia trachomatis are less likely than seronegative participants to conceive without IVF [25].

In a study on subfertile women with no visible tubal pathology, positive chlamydia antibody testing was associated with a 33% lower spontaneous pregnancy rate than those without chlamydia antibodies [26].

Several methods are used for the diagnosis of Chlamydia infection such as cell culture of cervicovaginal swab, serological testing by detection of specific antibodies: IgM for recent active infection, IgG for previous or chronic infection [27]. Sensing of the nucleic acid of chlamydia organisms via Polymerase chain reaction (PCR) is nevertheless a golden standard for diagnosis, though it is expensive and technically demanding [28].

Antibody testing for anti-Chlamydia antibodies has been found to be associated with tubal factor infertility [29]. Chlamydia IgG antibody test (CAT) is less cost prohibitive than PCR and has less risks than either HSG or laparoscopy [30].

This study was conducted on a randomly selected group of infertile women seeking ICSI, aiming to detect the prevalence of Chlamydia trachomatis infection using ELISA for detection of anti-Chlamydia IgG and IgM and using direct binding monoclonal-based immunochromatographic assay for detection of Chlamydia antigen in cervicovaginal swab.

The results of this study showed no statistically significant difference between age & BMI between study and control groups. This was agreed with Iran et al. [31] & Saleh et al. [32]; who found that there is no substantial difference in age and BMI of the study and control groups.

Regarding causes of infertility in the study group, it was found that the most common reason (23.5%) for infertility was polycystic ovaries (PCOS), while the travelling of the husband and endometriosis were the least (5%). It was also found that there were 8 instances (20%) with unexplained cause.

Miller JH et al. reported that the most usual case of female infertility was male factor (40%) and tubal & pelvic pathology (40%), however, ovarian dysfunction was (15%), unexplained infertility was (10%), unusual problem (5%) (376) Tubal factor infertility due to occlusion and peritoneal pathology causing adhesions is the most usual case of female infertility and diagnosed in approximately 30% to 35% of younger and older infertile women [33].

The lower incidence of positive chlamydia IgG in this field compared to surveys conducted in western rural areas could be assigned to lower frequency of predisposing factors of chlamydia infection including early sexual life and female multiple partners.

Regarding serum IgM, the comparison between the two studied groups showed that there were only 2 cases (5%) in the study group positive for serum chlamydial IgM, while in the control group there was only one case (5%) positive for serum chlamydial IgM, still with no significant difference. A study conducted by Annika Idahl, in Sweden, reported a higher prevalence of positive serum chlamydial IgM, which was about 13% [34].

In the present work, the higher incidence of positive chlamydia IgG in comparison to IgM could be attributed to IgM antibody being, reflecting acute infection while infertile patients have usually chronic infection. Also positive IgG result does not necessarily indicate a genital chlamydia trachomatis infection, as it could be an infection elsewhere in the physical structure.

The low prevalence of Chlamydia trachomatis (5%) in this study limits the survey of its impact on the success of ICSI cycles. Tasdemir et al. reported no significant impact on the ICSI outcome [35].

On the other hand, Rosenwaks et al. study showed a decrease in embryo characterization in positive cases for chlamydia (Ag), this was justified by heat shock protein induced by an inflammatory reaction in response to infection that may
impair embryo implantation and/or facilitates immune rejection after uterine transfer of in vitro fertilized embryos [36]. The very low prevalence rate of Chlamydia trachomatis infection in Egyptian females is justifiable by the cultural and religious impact on the sexual lifestyle in the Egyptian population. Also, Abed-Raboh and associates reported a very low prevalence rate of Chlamydia Trachomatis infection in the Egyptian females, which minimizes its role as a cause of infertility in the Egyptian population [37].
